

Question:

Barbed broach is used for:

Answer Choices:

- A. Extirpation of pulp
- B. Enlargement of canal
- C. Obturation of canals
- D. All of the above

Reasoning + Answer:

<tool_call>

A barbed broach is a dental instrument used primarily in endodontics. It is specifically designed to remove or clean the pulp tissue from the root canal system. The barbs on the broach help in effectively removing pulp tissue and debris from the canal, especially in cases where the canal is narrow or complex. It is not used for enlarging canals (that would be a file or reamer), nor is it used for obturation (which is done with gutta-percha and sealer). While it can assist in the removal of pulp, its primary function is extirpation, not canal enlargement or obturation. Therefore, option D (All of the above) is incorrect because the barbed broach is not used for canal enlargement or obturation.

The correct use of a barbed broach is for the extirpation of pulp tissue from the root canal. This is a standard procedure in endodontic therapy to remove infected or inflamed pulp tissue. It is not used to enlarge the canal or to obturate the canal.

Hence, the most accurate answer is A: Extirpation of pulp.

While some sources may describe barbed broaches as being used in canal preparation, in standard dental practice, their primary and intended use is pulp extirpation.

Therefore, the best and most precise answer based on clinical use is A.

<answer>

A. Extirpation of pulp

</answer>
